

# Discrete Morphology Models

# Discrete morphological data

- Binary characters
  - e.g. wings: present (1) or absent (0)
  - e.g. venation: palmate (0) or pinnate (1)
- Multistate characters
  - e.g. Number of incisors: 0, 1, 2, 3, 4, 5
  - e.g. plants: hermaphroditic (0), gynomonoecious (1), or dioecious (2)
- Discretized continuous characters
  - e.g. snout-vent length: short (0) or long (1)
  - e.g. leaf shape: entire (0), lobed (1), deeply dissected (2)

*Polygonella robusta* is gynomonoecious (female flowers at tip, bisexual flowers at base)

*Polygonella gracilis* is dioecious (male individual on left, female on right)

Leaf lobing in *Pelargonium*. From online supplement to Jones et al. 2009. *Evolution* 63: 479-497

# Symmetric vs. Asymmetric Models

	0	1
0	$-\beta$	$\beta$
1	$\beta$	$-\beta$

Symmetric  
(forward rate equals  
reverse rate)

	0	1
0	$-\alpha$	$\alpha$
1	$\beta$	$-\beta$

Asymmetric  
(forward rate potentially  
differs from reverse rate)

# State Frequencies

	0	1
0	$-\alpha$	$\alpha$
1	$\beta$	$-\beta$

← This instantaneous rate matrix...

...implies these equilibrium state frequencies:

$$\pi_0 = \frac{\beta}{\alpha + \beta}$$

$$\pi_1 = \frac{\alpha}{\alpha + \beta}$$

In other words, if you know  $\alpha$  and  $\beta$ , you also know  $\pi_0$  and  $\pi_1$ ,  
and if you know  $\pi_0$  and  $\pi_1$ , you also know  $\alpha$  and  $\beta$

# State Frequencies

Example: if rate of forward change ( $\alpha$ ,  $0 \rightarrow 1$ ) is twice the rate of the reverse change ( $\beta$ ,  $1 \rightarrow 0$ ), then  $\alpha = 2\beta$  and we have...

$$\pi_0 = \frac{\beta}{\alpha + \beta} = \frac{1}{3}$$

$$\pi_1 = \frac{\alpha}{\alpha + \beta} = \frac{2}{3}$$

In this case, fewer taxa are expected to have state 0 because of the greater tendency to change to 1

# For the record...

Here are general formulas for the transition probabilities for the two-state model:

$$P_{00}(t) = \frac{\beta}{\alpha + \beta} + \frac{\alpha}{\alpha + \beta} e^{-(\alpha + \beta)t}$$

$$P_{01}(t) = \frac{\alpha}{\alpha + \beta} \left( 1 - e^{-(\alpha + \beta)t} \right)$$

$$P_{10}(t) = \frac{\beta}{\alpha + \beta} \left( 1 - e^{-(\alpha + \beta)t} \right)$$

$$P_{11}(t) = \frac{\alpha}{\alpha + \beta} + \frac{\beta}{\alpha + \beta} e^{-(\alpha + \beta)t}$$

$$\alpha = \beta$$

$$\frac{1}{2} - \frac{1}{2} e^{-2\beta t}$$

$$\frac{1}{2} + \frac{1}{2} e^{-2\beta t}$$

$$\text{Expected number of changes/site} = \frac{2\alpha\beta t}{\alpha + \beta}$$

$$= \frac{2\beta^2 t}{2\beta} = \underline{\beta t}$$

# Multistate models

- Can extend the symmetric model to multiple states
  - 4-state version is identical to JC69 ←
  - $k$ -state version (where  $k$  is arbitrary) often called the Mk model (M=Markov) ← ME
- Can extend the asymmetric model also

**Example of the model of evolution for a trait that adopts three states**

<i>State</i>	<i>0</i>	<i>1</i>	<i>2</i>
0	--	q <sub>01</sub>	q <sub>02</sub>
1	q <sub>01</sub>	--	q <sub>12</sub>
2	q <sub>20</sub>	q <sub>21</sub>	--

From the BayesTraits manual:

<http://www.evolution.reading.ac.uk/Files/BayesTraits-V1.0-Manual.pdf>

# Molecules vs. Morphology

These two A nucleotides represent the **same state**

A **AC**CA**T**  
B ACCAT  
C ATCAT  
D ATCAT  
E ATCGT

These two 0 states have **nothing to do with each other**

A	0	0	0	0	0	1
B	0	0	0	0	0	1
C	1	0	0	1	1	0
D	0	0	0	1	1	0
E	1	0	0	1	1	0

For morphology, makes no sense to compute empirical frequencies

# What to do about state frequencies?

1. Don't even try to estimate state frequencies

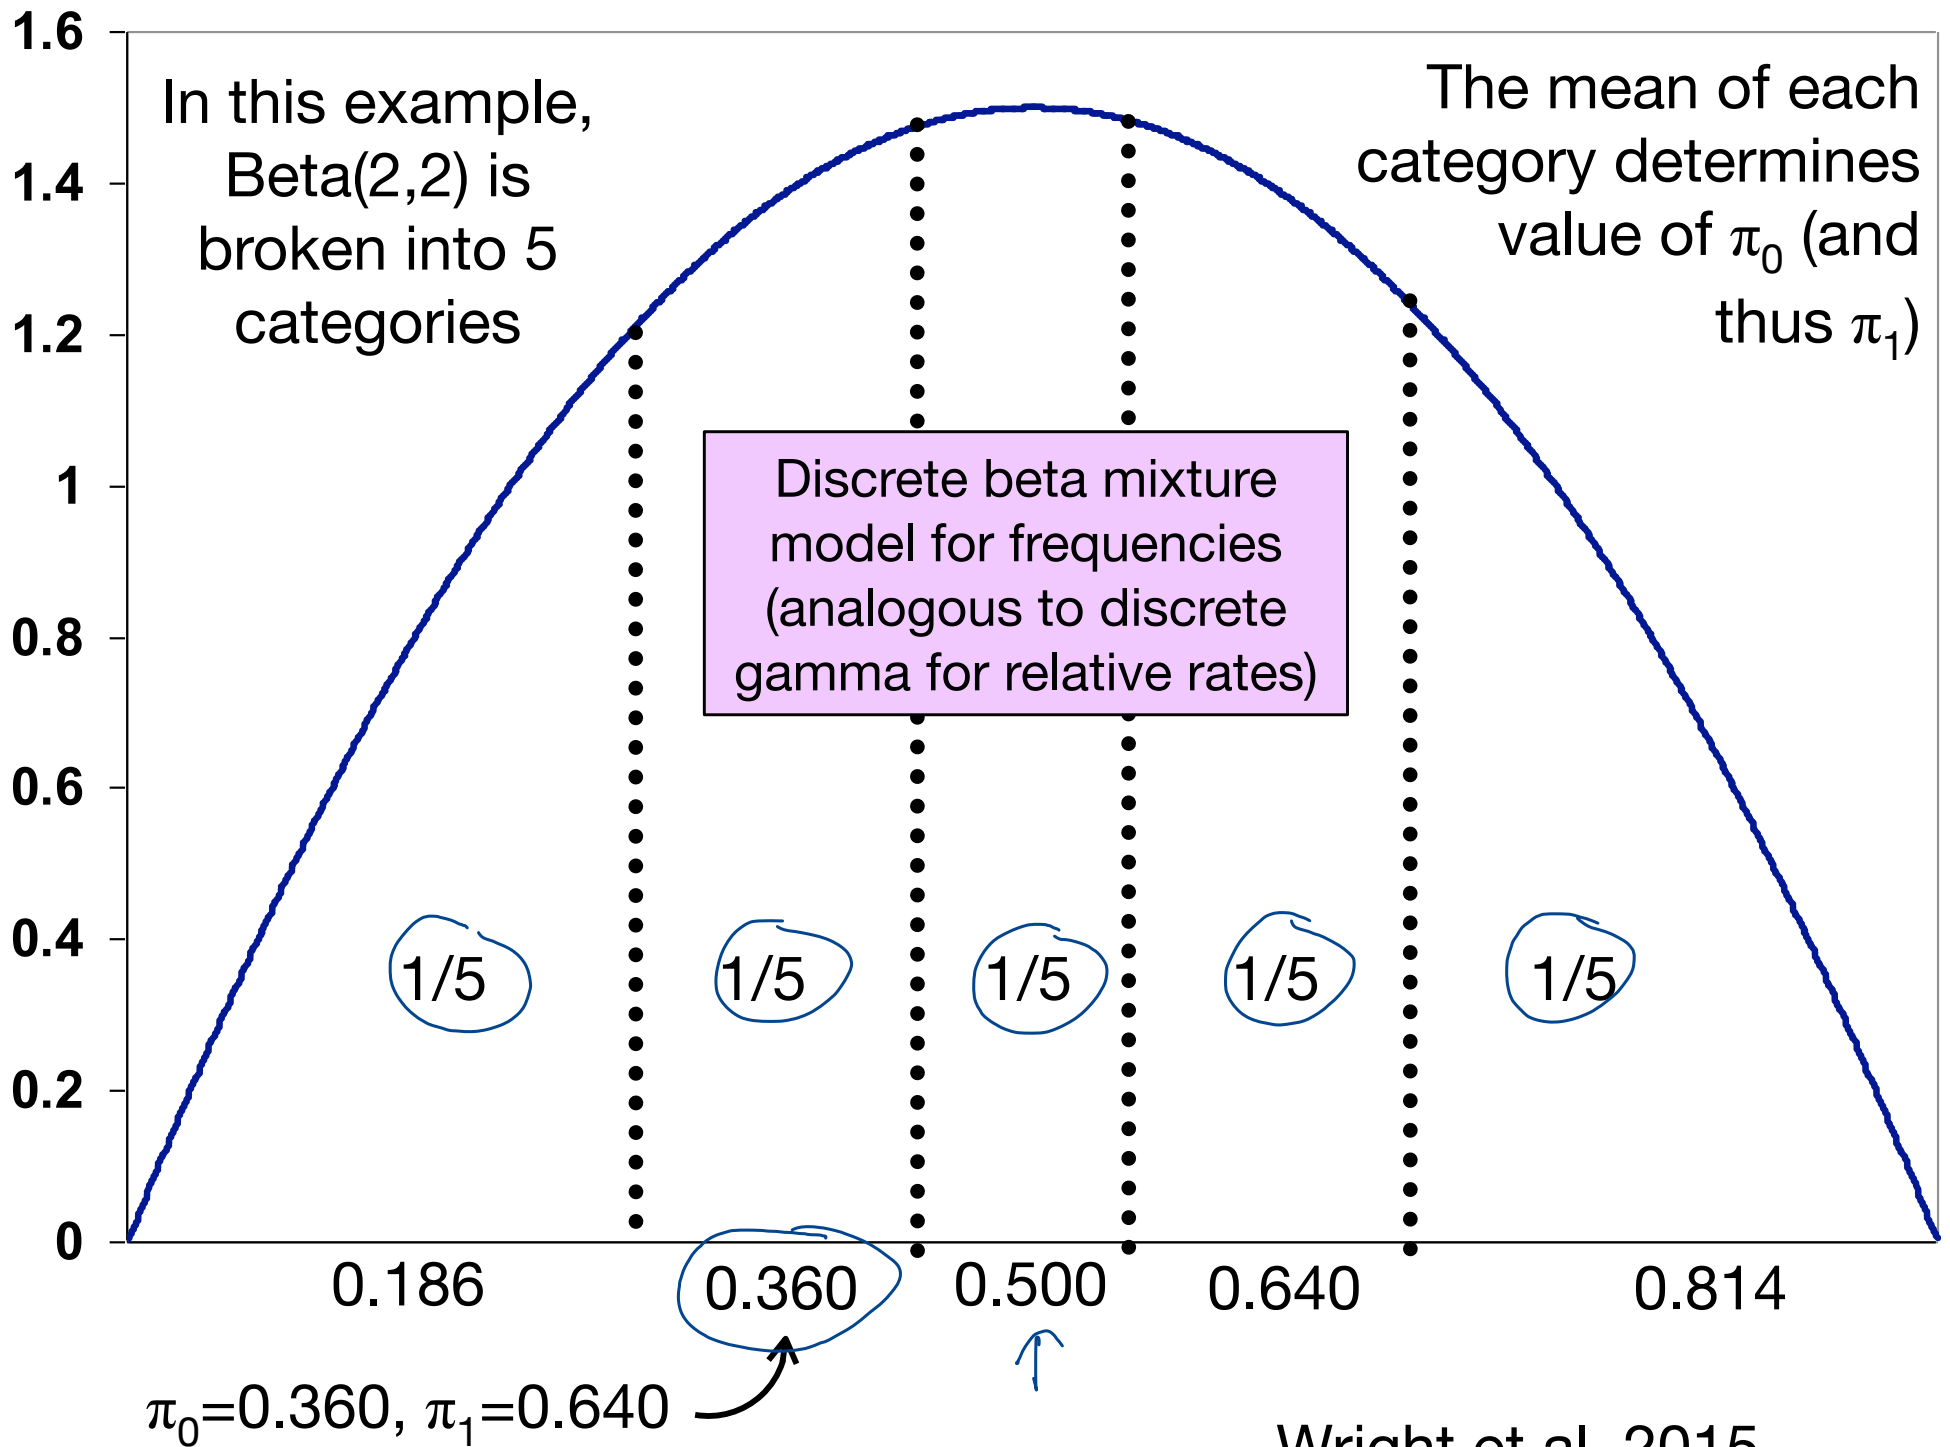

Assume symmetric model; i.e.  $\pi_0 = \pi_1 = 0.5$

2. Estimate state frequencies separately for each character

Asymmetric model, but adds one parameter for every character

3. Use a mixture model

Use **discrete beta distribution** for frequency heterogeneity in the same way that the **discrete gamma distribution** is used for rate heterogeneity

# Ascertainment Bias in Morphology Datasets

P._basiramia	001110112000001000110

**No constant characters:** no characters have same state for all taxa

**No autapomorphies** (i.e. only one taxon different) either

This represents an **ascertainment bias**: characters included are biased towards those that are parsimony informative.

# Estimating branch lengths from discrete morphological data

What if you simulated data using a JC69 model and this model tree, then *withheld all constant sites* from PAUP\* and asked it to estimate branch lengths under the same JC69 model?

# Estimating branch lengths from discrete morphological data

Doing that produces results like this:

Edge	True length	ML estimate
A	0.2	241,750
B	0.05	0.4321
C	0.2	54.646
D	0.05	143,950
interior	0.05	0.022

Estimated edge lengths are crazy!

Lewis 2001a

# Conditioning on variability

$P(D, C)$

$$\Pr(D, V) = \Pr(D|V) \Pr(V)$$

want

Probability of the data *and* character is variable

Probability of the data *given* character is variable

Probability that character is variable

$$\Pr(D|V) = \frac{\Pr(D, V)}{\Pr(V)}$$

Likelihood computed the normal way

Likelihood conditional on character variability

Probability of choosing an **orange** circle = 0.3

Probability of choosing an **orange** circle **given** that the circle chosen is **not gray** =  $0.3/0.6 = 1/2$

# Poisson Example

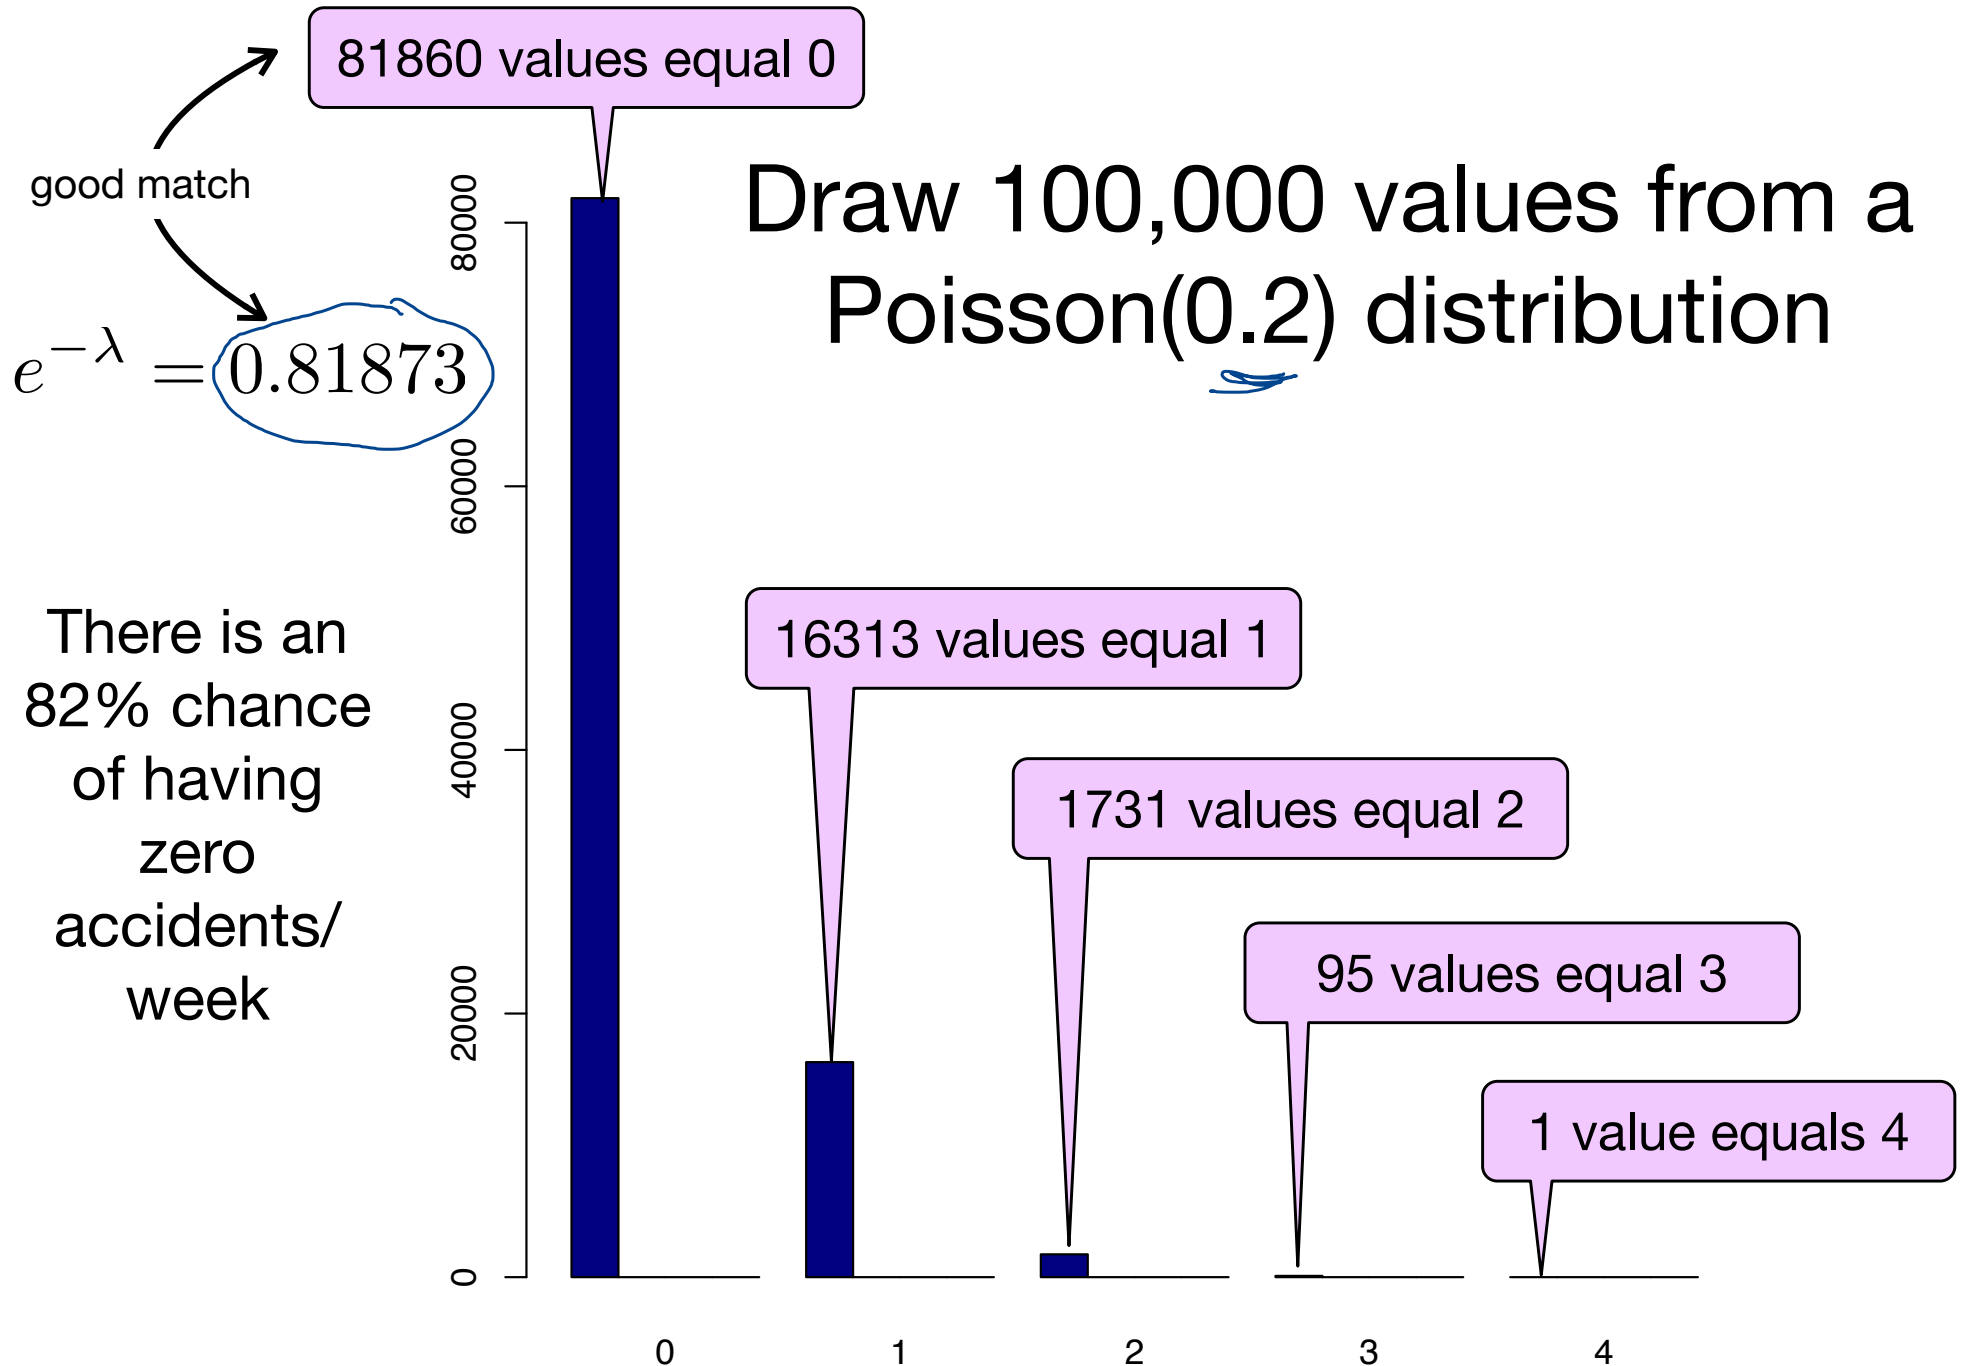

Let  $y$  be the **number of accidents** at an intersection/week.  
**Lambda** ( $\lambda$ ) is the **mean** number of accidents/week.

$$1 = \frac{\lambda^0 e^{-\lambda}}{0!} + \frac{\lambda^1 e^{-\lambda}}{1!} + \frac{\lambda^2 e^{-\lambda}}{2!} + \frac{\lambda^3 e^{-\lambda}}{3!} + \dots$$

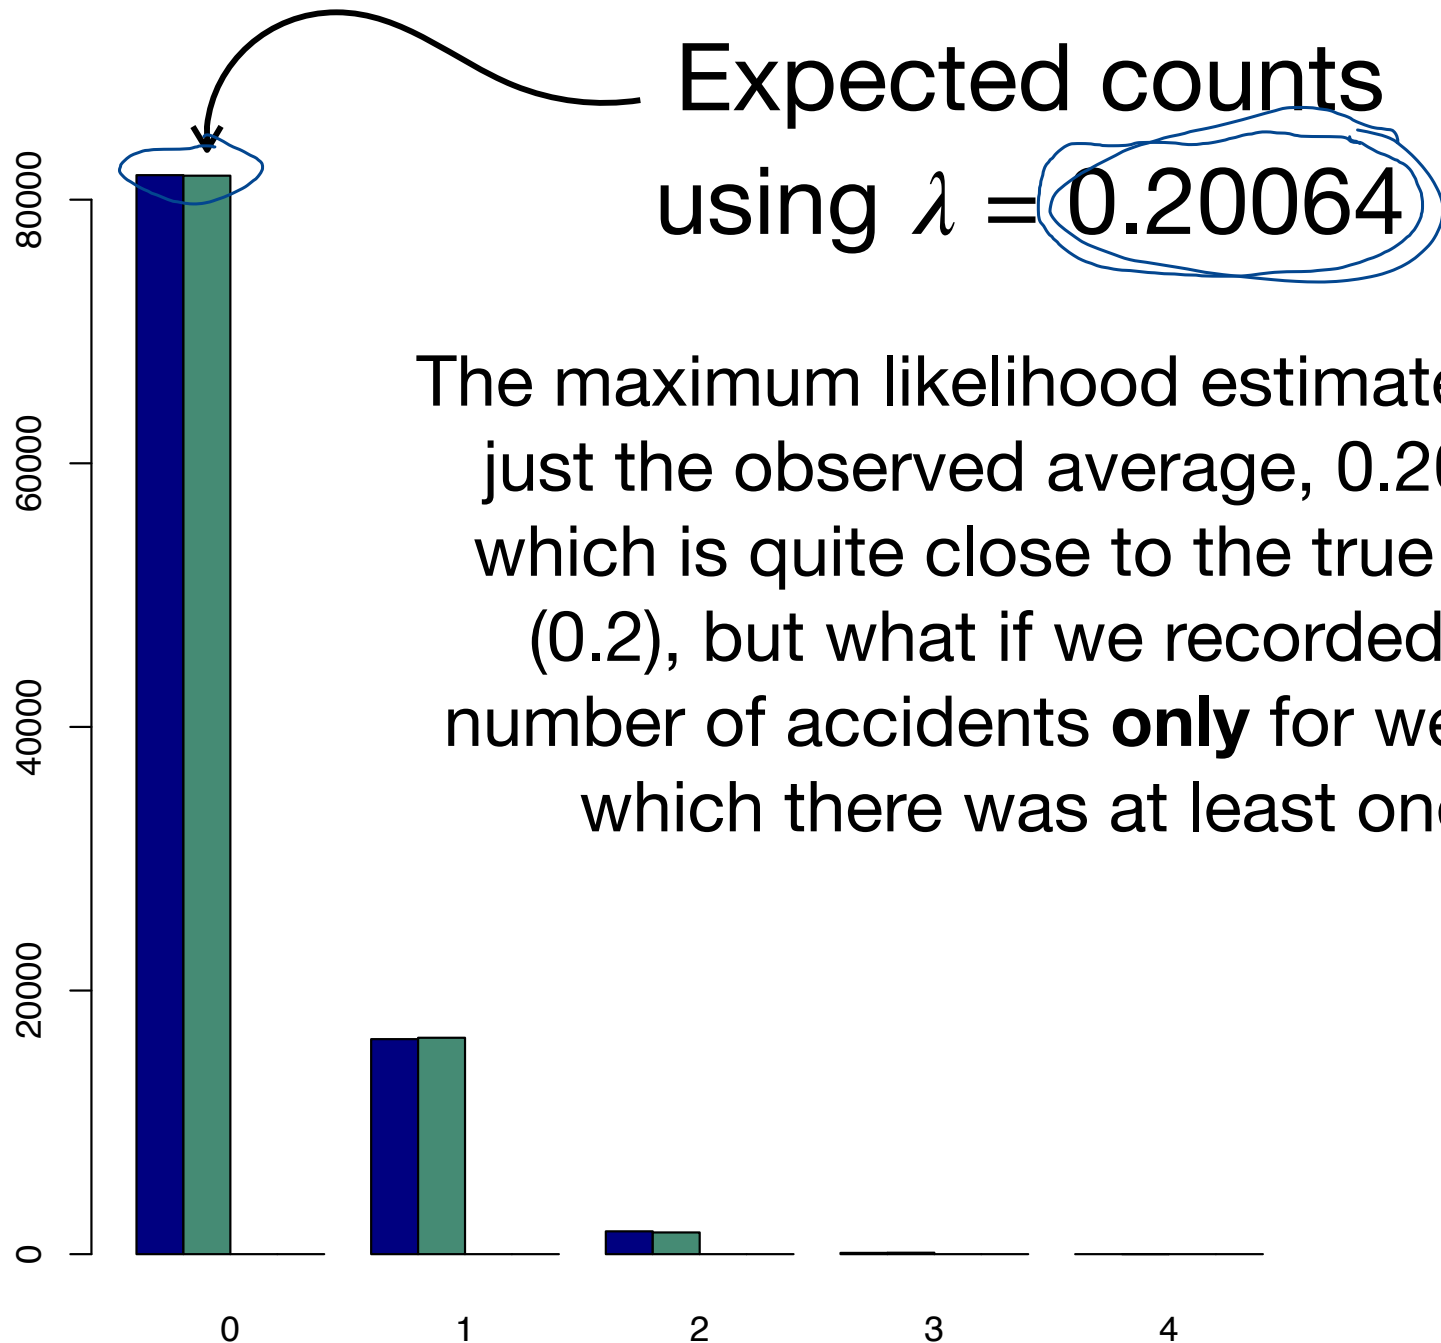

These are the probabilities of 0, 1, 2, 3, ..., accidents/week given lambda (the infinite sum equals 1, as it should).

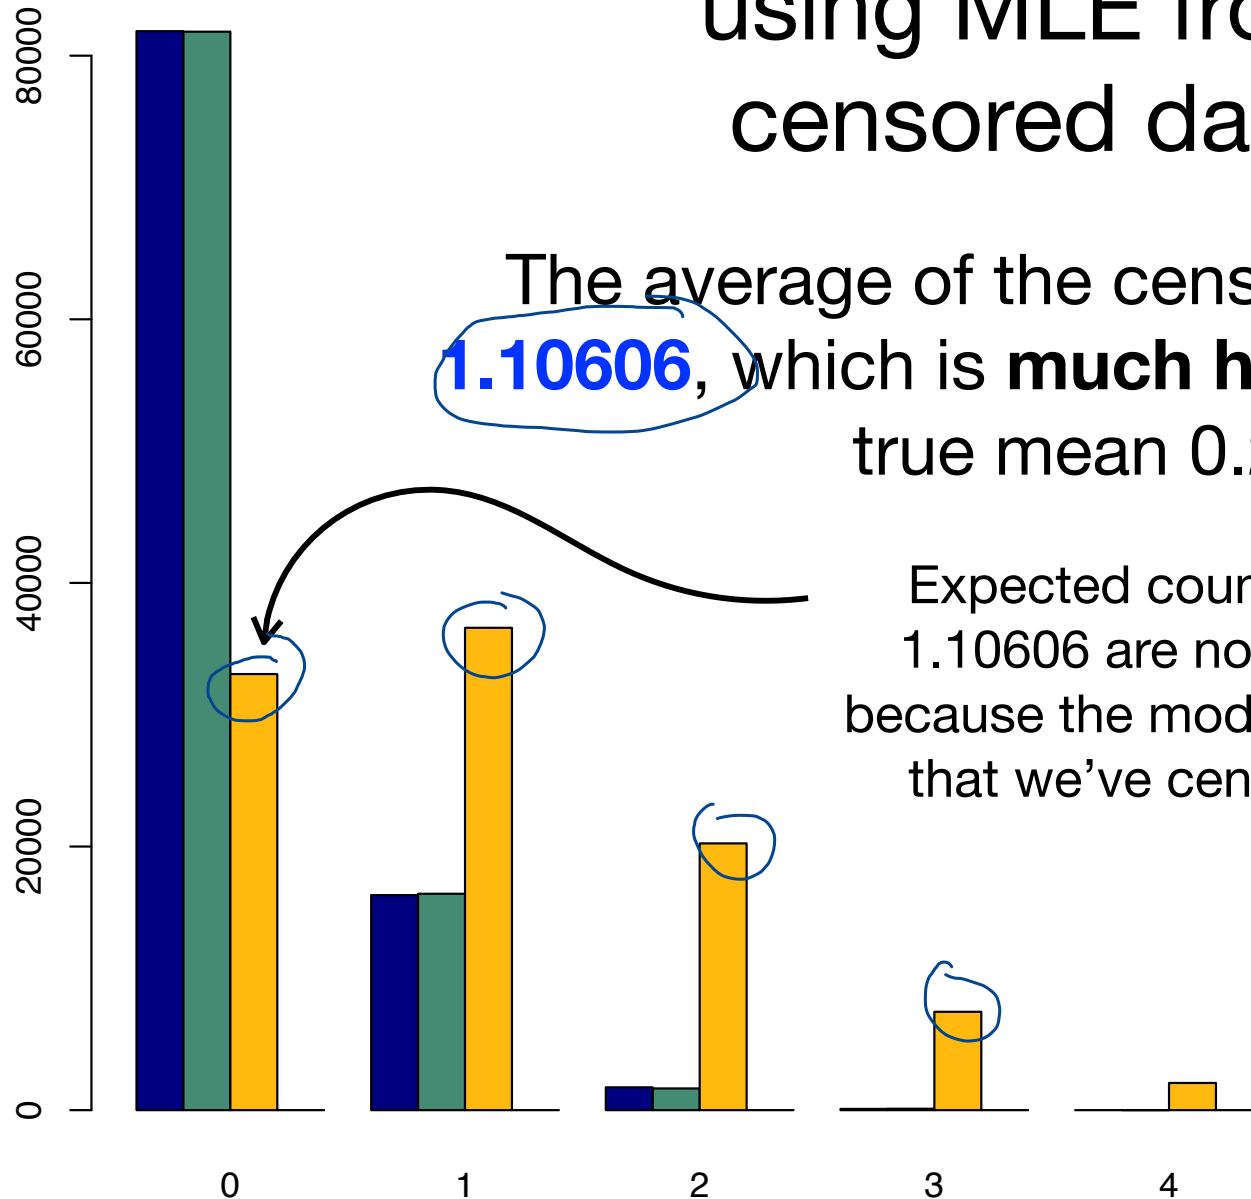

# Draw 100,000 values from a Poisson(0.2) distribution

There is an 82% chance of having zero accidents/week

# Expected counts using MLE from censored data

The average of the censored data is **1.10606**, which is **much higher** than the true mean 0.2

Expected counts using mean 1.10606 are not very accurate because the model does not know that we've censored the data

# Poisson Example

$$1 = \frac{\lambda^0 e^{-\lambda}}{0!} + \frac{\lambda^1 e^{-\lambda}}{1!} + \frac{\lambda^2 e^{-\lambda}}{2!} + \frac{\lambda^3 e^{-\lambda}}{3!} + \dots$$

The equation shows the sum of probabilities for a Poisson distribution. The first term,  $\frac{\lambda^0 e^{-\lambda}}{0!}$ , is circled in blue. The terms from  $\frac{\lambda^1 e^{-\lambda}}{1!}$  onwards are grouped together in a larger blue oval. Handwritten blue arrows point from the circled term to the terms in the larger oval.

$$1 - e^{-\lambda} = \frac{\lambda^1 e^{-\lambda}}{1!} + \frac{\lambda^2 e^{-\lambda}}{2!} + \frac{\lambda^3 e^{-\lambda}}{3!} + \dots$$

The expression  $1 - e^{-\lambda}$  is enclosed in a purple rounded rectangle. An arrow points from this rectangle to the text below. The right-hand side of the equation is circled in blue.

We should be using this as our total probability

# Poisson Example

1

2

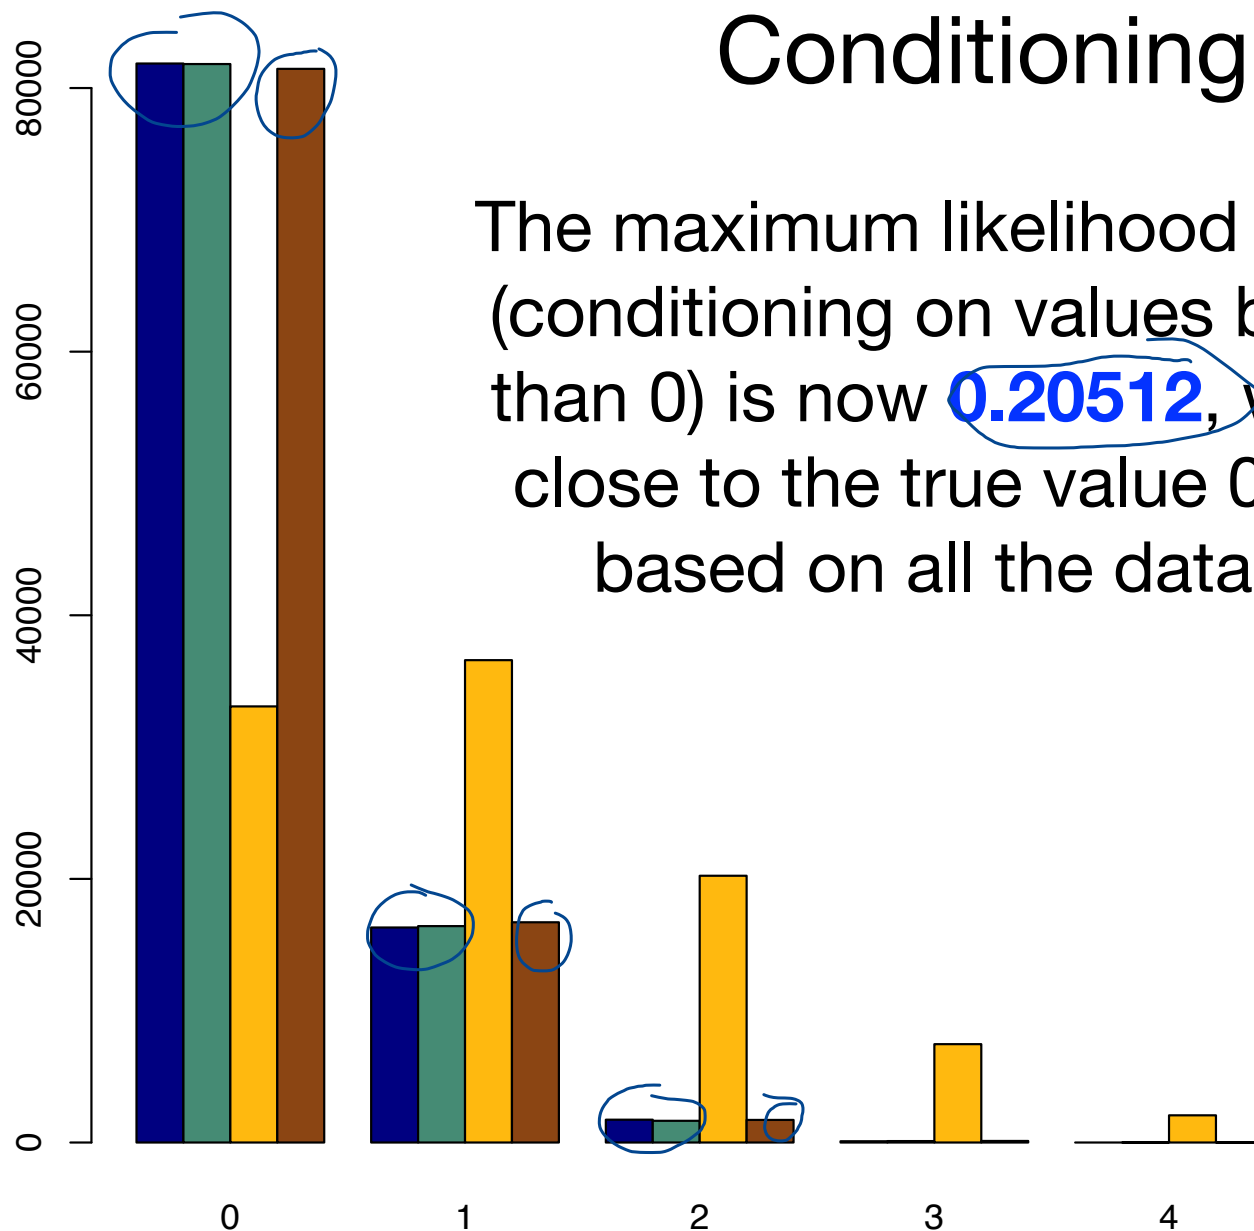

3

$$1 = \frac{\lambda^1 e^{-\lambda}}{1!(1 - e^{-\lambda})} + \frac{\lambda^2 e^{-\lambda}}{2!(1 - e^{-\lambda})} + \frac{\lambda^3 e^{-\lambda}}{3!(1 - e^{-\lambda})} + \dots$$

The equation shows the sum of three terms. Each term has a denominator of  $n!(1 - e^{-\lambda})$  for  $n=1, 2, 3$ . Blue underlines are drawn under the  $(1 - e^{-\lambda})$  part of each denominator. Black arrows point upwards from the underlines to the  $(1 - e^{-\lambda})$  terms in the text below.

Dividing each by the probability of at least one accident serves to inform the model that we've omitted the zeros

# Conditioning helps!

The maximum likelihood estimate of  $\lambda$  (conditioning on values being greater than 0) is now **0.20512**, which is very close to the true value 0.2 and MLE based on all the data, 0.20064

# Conditioning on variability

Probability of the data *and* character is variable

$$\Pr(D|V) = \frac{\Pr(D, V)}{\Pr(V)}$$

Probability that character is variable

Probability of the data *given* character is variable

1 - Pr(character is constant)

How do we calculate Pr(C), the probability that a character is constant?

# Calculating $\text{Pr}(C)$

$\text{Pr}(C)$  is the probability that a constant character like this one would arise based on the current tree topology and edge lengths.

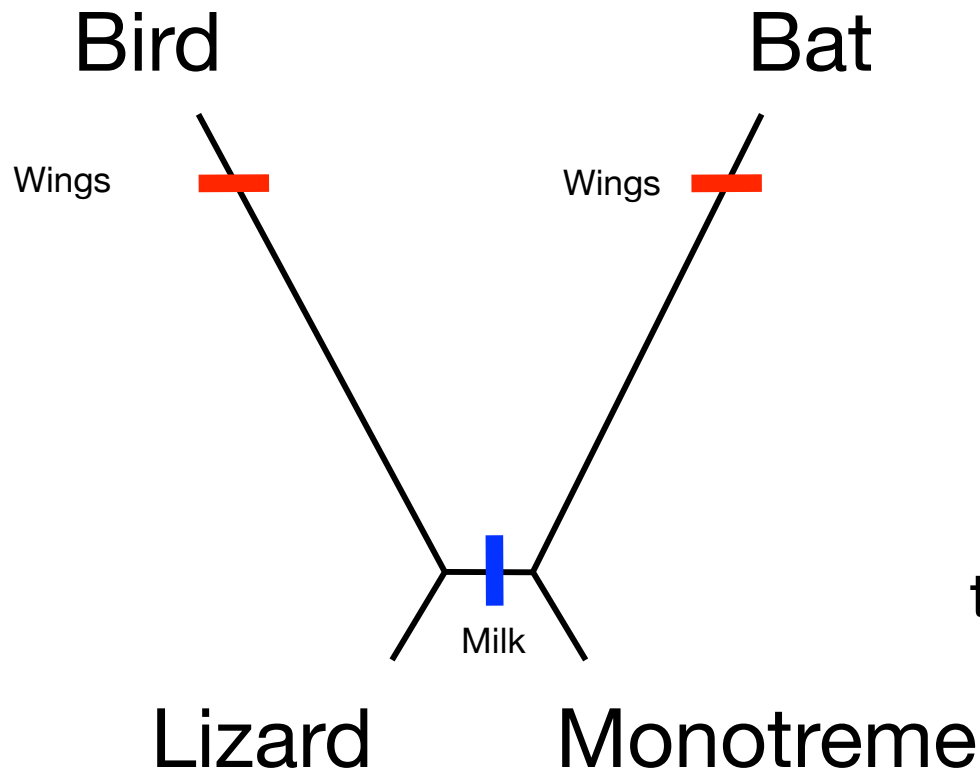

# Estimating branch lengths from discrete morphological data

Here is the result of conditioning on variability:

Edge	True length	Naïve model	Corrected model
A	0.2	241,750	0.206
B	0.05	0.4321	0.05 ↩
C	0.2	54.646	0.206 ↩
D	0.05	143,950	0.051
interior	0.05	0.022	0.052

Much better!

# The Autapomorphy Trail

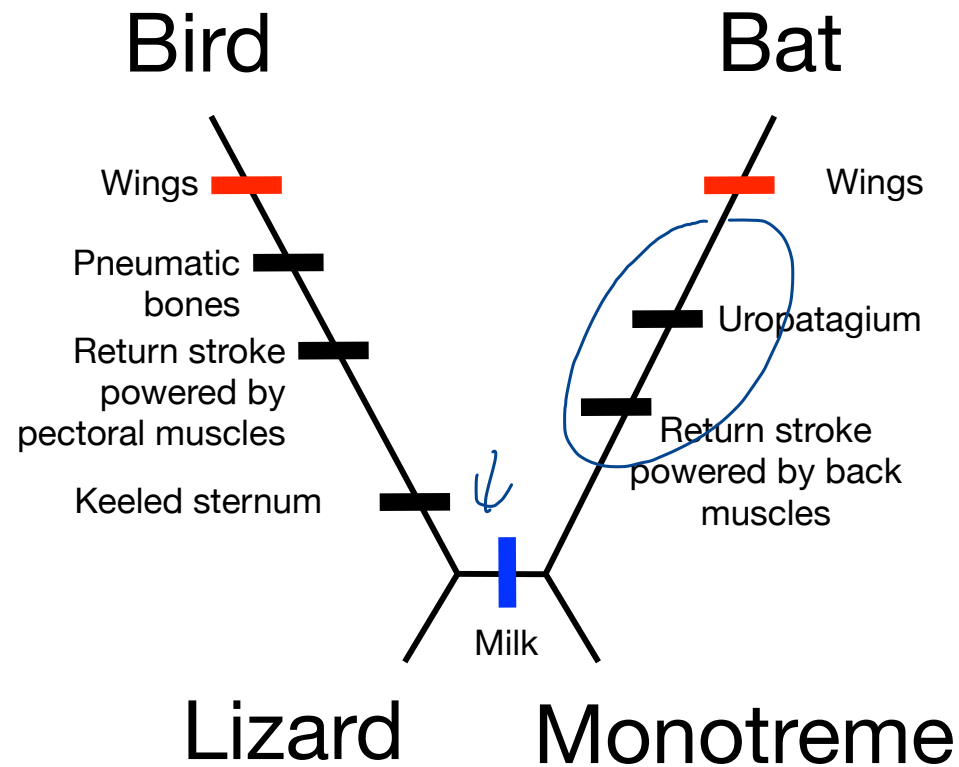

**Wings** and **milk** are both parsimony informative, but conflict - one must be homoplasious. Parsimony would not be able to decide between the tree supported by wings and the alternative tree (shown here) supported by milk.

# The Autapomorphy Trail

We know that wings is the homoplasy here, and both birds and bats evolved wings independently to allow them to fly.

Evidence for this independent adaptation lies in the **trail of autapomorphies** related to flight.

If convergence events are often associated with such a trail of autapomorphies, then using branch length information is helpful.
